1 Introduction

The March 2020 federal student loan repayment pause became the longest suspension of mandatory student debt payments in U.S. history. Over three years, borrowers with federally held loans faced no required payments, easing short-run cash-flow pressure. In 2023, the Fiscal Responsibility Act ruled out further extensions of the pause. The Supreme Court blocked the Biden administration's debt-relief plan in June, interest resumed in September, with the first payments due in October [Congressional Research Service, 2022]. For heavily indebted borrowers, this marked a sharp decline in expected cash flow and a shift from pause and possible forgiveness to repayment certainty [Aladangady et al., 2025].

This paper examines whether that shift reduced incorporated self-employment among high-debt borrowers. The question is economically important because entrepreneurship depends on household financial capacity under imperfect capital markets [Evans and Jovanovic, 1989]. Beyond its documented consumption effects, the repayment restart may also have affected labour supply choices at the self-employment margin, where entry and continuation are especially sensitive to liquidity, balance-sheet strength, and willingness to bear income risk [Aladangady et al., 2025, Evans and Jovanovic, 1989].

Existing empirical work suggests that student debt can suppress entrepreneurship. Krishnan and Wang [2018] provide micro-level evidence, using policy-induced variation in student debt levels and bankruptcy dischargeability to show that student debt reduces the probability of firm formation, particularly for larger and more capital-intensive ventures. Ambrose et al. [2015] find that areas experiencing larger increases in student debt saw weaker small-business formation. However, their analysis is at the county level and cannot link individual borrowers to outcomes. More recent evidence on the 2023 restart itself has focused on consumption rather than entrepreneurship. Aladangady et al. [2025] show that spending responses began after the June 2023 policy-resolution period, before October payments were actually due. These studies show that student debt can slow entrepreneurship and that the 2023 restart affected behaviour, but do not examine individual-level self-employment.

This paper addresses that gap by studying the effect of the 2023 repayment-restart environment on incorporated self-employment using individual-level panel data. The data are obtained from the Survey of Income and Program Participation (SIPP) [U.S. Census Bureau, 2024] for 2018–2023 to estimate a Difference-in-Differences design, comparing heavily indebted borrowers with non-borrowers before and after 2023. We find little evidence of an effect at moderate debt levels, but a substantially larger negative effect among borrowers in the top tercile of

the debt distribution.

2 Theoretical Framework

Evans and Jovanovic [1989] argue that entrepreneurial entry depends on personal wealth, as credit constraints limit individuals' access to external financing for new investments. This provides the theoretical foundation for our empirical predictions, grounded in a liquidity-constrained view of entrepreneurship. The restart of student loan repayment is a shock to individuals' discretionary income and, therefore, lowers their ability to finance investments internally. Incorporated self-employment usually requires higher upfront capital and fixed costs than unincorporated self-employment. Thus, it should be most affected by the shock. Additionally, the repayment restart also changed the certainty of future payments, making anticipatory effects plausible for forward-looking households [Bernanke, 1983]. Using this economic intuition, we expect incorporated self-employment to decline in 2023 among borrowers with the largest student debt burdens, with the effect concentrated in the upper tail of the debt distribution. Moreover, if borrowers respond by shifting away from more capital-intensive activity rather than exiting self-employment altogether, incorporated self-employment should fall while unincorporated self-employment remains stable or rises.

3 Data and Empirical Strategy

3.1 Data

The SIPP is a longitudinal household survey conducted by the U.S. Census Bureau. Under the modern SIPP design, individuals are interviewed annually, with most questions referring to the preceding calendar year and many labour- market variables recorded at monthly frequency within that reference period (U.S. Census Bureau, 2024). We use the 2018–2023 SIPP files, spanning the pre- restart period and the first year of repayment resumption. The raw dataset con- tains 90,798 person-month observations across approximately 4,903 individuals.

The sample is restricted to individuals aged 22–45, focusing on the population most likely to hold student debt and to make labour-market and business-entry decisions. The main analysis is conducted at the person-year level. Monthly observations are collapsed into annual measures using means for outcomes and time-varying continuous variables, and the first observation for characteristics

that are largely fixed within the year. This yields 5,055 person-year observations. Collapsing to the person-year level is deliberate: incorporated self-employment is infrequent at the monthly level, and annual outcomes align more closely with the treatment timing used in the empirical design.

Our primary outcome is incorporated self-employment. We also examine unincorporated self-employment and total self-employment as contrast outcomes. This distinction is useful because tighter financial conditions should matter for more capital-intensive forms of self-employment.

Treatment is defined using student debt observed before 2023. The treatment group consists of borrowers in the top tercile of the pre-period debt distribution, corresponding to balances of approximately $66,000 or above. We also consider a broader comparison using borrowers above the median debt level (Table 2), while the control group consists of individuals with no student loan debt. Defining treatment using pre-period debt ensures that treatment status is determined prior to the repayment-restart environment rather than by outcomes observed after the policy change.

3.2 Treatment Definition and Sample Construction

Our main design compares heavily indebted borrowers with non-borrowers before and after 2023. The top-tercile definition is the central specification, while the above-median definition serves as a threshold check (Appendix A Figure 4). These cut-offs are used to assess whether any effect is concentrated among borrowers with the largest debt burdens. In both cases, the control group consists of individuals with no student loan debt. We define 2023 as the post period. Given the annual structure of SIPP, this should be interpreted as capturing the broader repayment-restart environment rather than the isolated effect of October payments alone.

3.3 Entropy Balancing

Heavily indebted borrowers differ substantially from non-borrowers on pre-period observables. To improve comparability, we use entropy balancing [Hainmueller, 2012], which reweights control observations so that their covariate means match those of the treated group exactly. We estimate weights using each individual's first pre-period observation and balance on age, education, gender, marital status, homeownership, employment status, net worth, household income, and race and ethnicity indicators. As shown in Appendix A Figure 5, observable imbalance is substantially reduced after reweighting. Because entropy balancing

addresses only observable differences, we use it as a robustness device alongside the panel fixed-effects design.

3.4 Empirical Specification

The main specification is a Two-Way Fixed Effects Difference-in-Differences (TWFE) model of the form:

$$se_inc_{it} = \alpha_i + \lambda_t + \beta(\text{HighDebt}_i \times \text{Post}_t) + X'_{it}\gamma + \varepsilon_{it}$$

where se_inc_{it} is incorporated self-employment for individual i in year t, α_i are individual fixed effects, λ_t are year fixed effects, and X'_{it} contains time-varying controls. Standard errors are clustered at the individual level throughout.

We report a progression of specifications. Pooled OLS provides a baseline comparison. Entropy-weighted OLS shows how observable imbalance affects the cross-sectional estimate. Unweighted two-way fixed effects is the main panel DiD specification. Entropy-weighted TWFE serves as an observable-balance robustness check. Finally, we report a Mundlak-correlated random-effects model as an additional robustness check that retains observations while allowing correlation between individual effects and regressors via person-level means of time-varying covariates [Mundlak, 1978, Wooldridge, 2019].

The TWFE model aims to capture the causal effect of the 2023 debt-uncertainty environment across individuals in different debt groups while controlling for time and individual fixed-effects [Imai and Kim, 2021], thereby motivating its use as the primary model in the empirical research.

3.5 Identification Assumptions

Table 1: Identification Assumptions for the DiD Estimator

Assumption	Description
A1: No-Anticipation	For all i, t and $t < 2023$: $Y_{i,t}(1) = Y_{i,t}(0)$. No behavioual response before the treatment.
A2: Parallel Trends	For each $t \in \{2018, \ldots, 2022\}$: $\mathbb{E}[Y_t(0) - Y_{t-1}(0) \mid HighDebt = 1] = \mathbb{E}[Y_t(0) - Y_{t-1}(0) \mid HighDebt = 0]$. Counterfactual trends are parallel absent the restart.
A3: Overlapping	For each $t \in \{2018, \ldots, 2023\}$, $\text{supp}(X \mid HighDebt = 0) \supseteq \text{supp}(X \mid HighDebt = 1)$ Sufficient overlap exists such that entropy balancing weights can be constructed for all observations.

Our identification relies on the assumptions listed in Table 1. To address the no-anticipation assumption, We estimate a placebo specification assigning the post-period to 2022 and excluding 2023, the placebo coefficient is statistically insignificant, reducing concern that the main result reflects an unrelated structural break at the 2022–2023 boundary. The parallel trends assumption is assessed through an event-study specification with 2022 as the reference year. The pre-period coefficients for 2018–2021 are jointly insignificant (F-test p = 0.452), providing no evidence of differential pre-trends. Because pre-period covariates differ substantially across groups, entropy balancing is used to improve observable comparability, while the fixed-effects design addresses time-invariant unobserved heterogeneity [Hainmueller, 2012].

4 Results

4.1 Descriptive Trends

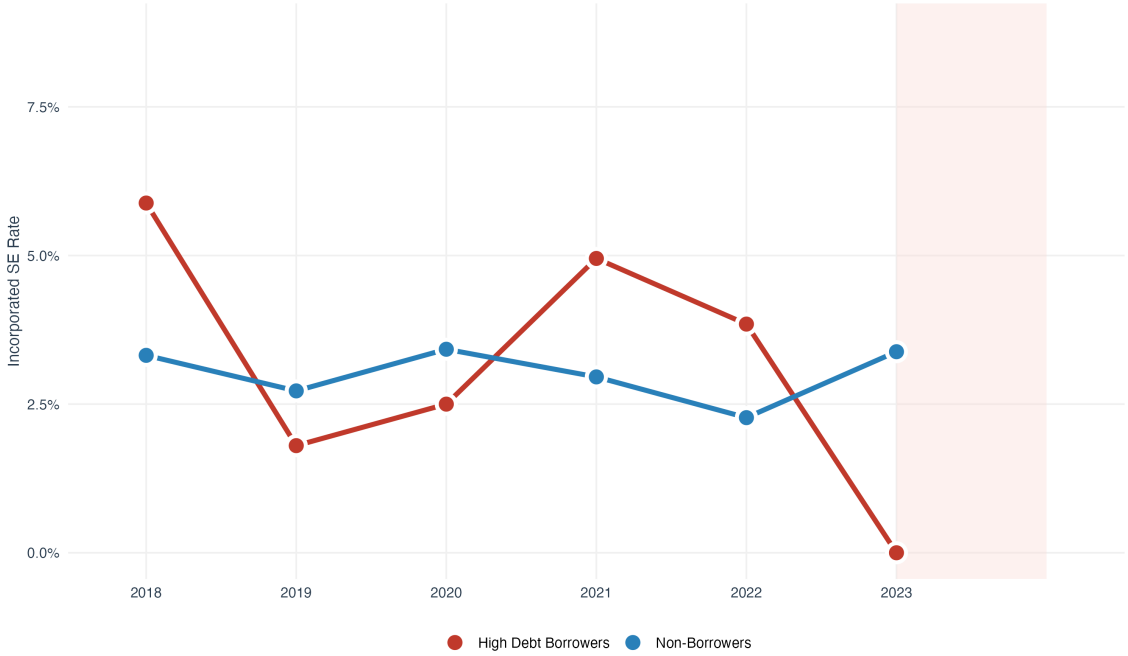

Figure 1: Incorporated self-employment rate by group, 2018-2023

Figure 1 plots average incorporated self-employment rates for heavily indebted borrowers and non-borrowers over 2018–2023. The treated series is more volatile than the control series in the pre-period, with a temporary decline in 2019, but there is no clear evidence of a sustained downward differential trend before 2023. The key visual pattern is the sharp divergence in 2023: incorporated self-employment among top-tercile borrowers falls to zero, while the corresponding rate among non-borrowers remains broadly stable. These descriptive patterns should be interpreted cautiously, however, because the treated group is relatively small and incorporated self-employment is a low-frequency outcome. For that reason, the main conclusions rely on the regression-based estimates and formal pre-trend tests rather than on raw annual means alone.

4.2 Treatment Thresholds

Table 2 presents the threshold identification strategy, comparing the estimated effect of the 2023 repayment-restart environment across two alternative treatment definitions to assess where in the debt distribution the negative association

with incorporated self-employment is strongest. Among above-median borrowers (debt threshold of approximately $29,000), coefficients are uniformly small and statistically insignificant across specifications, ranging from -0.009 to -0.037, providing little evidence that moderate debt exposure generated a detectable decline in incorporated self-employment. This suggests that the estimated effect is not broadly shared across all borrowers, but instead becomes visible only among those facing the largest repayment obligations. Restricting treatment to the top tercile of the debt distribution ($66,000 and above, median balance $102,500), the estimated effect becomes larger. The unweighted TWFE estimate is -0.124 (s.e. 0.054), implying a 12.4 percentage point decline in incorporated self-employment relative to non-borrowers in 2023. The entropy-weighted TWFE estimate, which adjusts for observable compositional differences between groups, remains economically similar at -0.102 (s.e. 0.091), although it is no longer statistically significant. The Mundlak correlated random effects estimate is -0.024 (p = 0.024), again negative and statistically significant. Taken together, this pattern is more consistent with a threshold-type response than with a smooth linear relationship across the debt distribution. Although the evidence does not identify a precise structural cutoff, it suggests that the detectable decline in incorporated self-employment is concentrated among the most heavily indebted borrowers. The remainder of the analysis therefore, adopts the top-tercile definition as the preferred treatment measure.

4.3 Main Estimates

Table 2: Main Results and Threshold Identification

	Above Median ($29k+)			Top Tercile ($66k+)

$p < 0.10$, $p < 0.05$, $^{**}p < 0.01$

Notes: Clustered standard errors at the person level in parentheses. Control group = non-borrowers throughout. Columns (1)–(3) use above-median debt as treatment ($29,000); columns (4)–(8) use the top tercile ($66,000+).

Table 2 reports estimates when taking the top-tercile as the threshold. Across all specifications, the estimated effect of the 2023 repayment-restart environment on incorporated self-employment is negative, although its magnitude and precision vary across estimators. The pooled OLS estimates are -0.047 (s.e. 0.012) and -0.049 (s.e. 0.015) in the entropy-weighted version, both precisely estimated, indicating that heavily indebted borrowers exhibit lower incorporated self-employment in 2023 relative to non-borrowers. However, these cross-sectional estimates remain vulnerable to unobserved time-invariant differences between the two groups.

The main panel estimate comes from the unweighted two-way fixed effects specification, which yields -0.124 (s.e. 0.054), implying a 12.4 percentage point decline in incorporated self-employment among top-tercile borrowers in 2023 relative to non-borrowers, compared with their pre-period difference. Relative to pooled OLS, the larger fixed-effects estimate suggests that time-invariant individual heterogeneity was attenuating the cross-sectional relationship rather than generating it spuriously. Once observable imbalance is addressed through entropy balancing, the fixed-effects estimate remains economically similar at -0.102 (s.e. 0.091), but is no longer statistically precise, suggesting that the negative effect is broadly robust in sign and approximate magnitude but less precisely estimated once the control group is reweighted to resemble treated borrowers more closely. The weighted Mundlak correlated random effects estimate is -0.024 (s.e. 0.011), again pointing to a negative relationship, although its smaller magnitude suggests some caution in treating any single coefficient as definitive. Overall, the specification progression points to the same broad conclusion: incorporated self-employment was lower in 2023 among borrowers with the highest debt burdens, although variation in magnitude and precision across estimators implies that the exact size of the effect should be interpreted cautiously.

4.4 Event Study and Parallel Trends

Figure 2 reports the dynamic treatment effect using 2022 as the reference year. The coefficients for 2018–2021 are small in magnitude and jointly insignificant, providing no evidence of differential pre-trends before 2023. This supports the identifying assumption that, with the absence of the repayment-restart environment, heavily indebted borrowers and non-borrowers would have followed similar trends in incorporated self-employment. By contrast, the 2023 coefficient is sharply negative, indicating that the divergence between treated and control groups emerges only in the year of the restart environment. This is an important result because it helps distinguish the main estimate from a pre-existing trend. At the same time, the annual structure of the data means the event study should

not be interpreted as identifying the precise moment within 2023 at which behaviour changed. Its role is to show that the break is specific to 2023, not to isolate whether the adjustment occurred in June, September, or October.

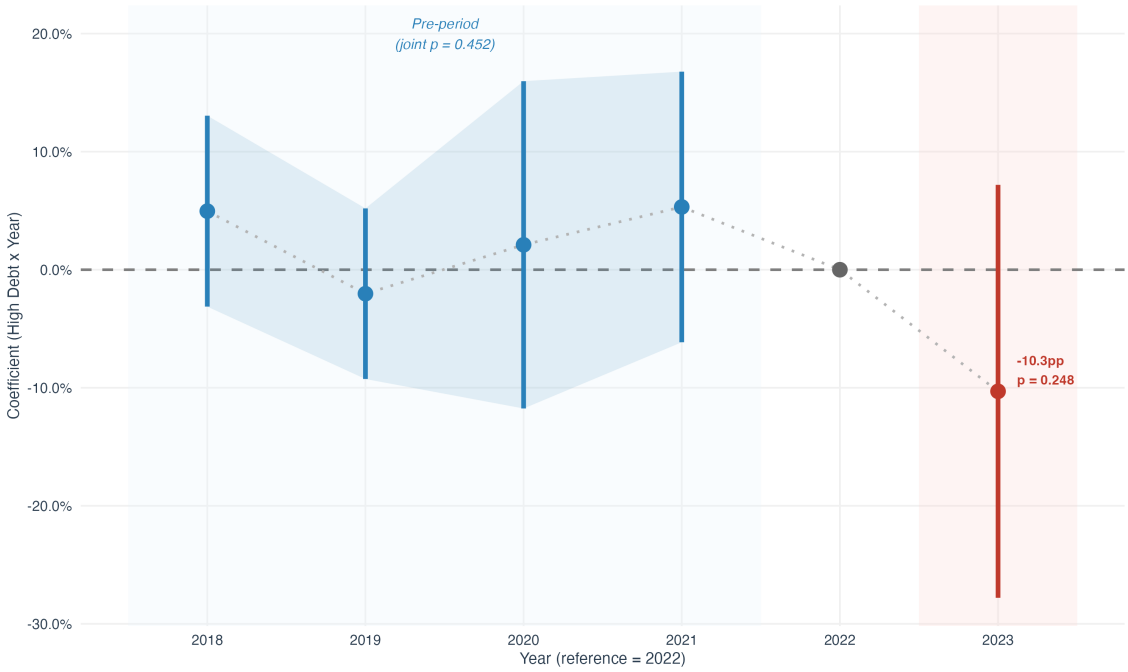

Figure 2: Event study: Parallel Trends

4.5 Composition Across Self-Employment Outcomes

Figure 3 compares incorporated, unincorporated, and total self-employment. The estimated effect is -10.2 percentage points for incorporated self-employment, +15.2 percentage points for unincorporated self-employment, and +5.0 percentage points for total self-employment. Although the latter two estimates are not precisely estimated, the overall pattern is more consistent with compositional reallocation than with a broad collapse in self-employment. This evidence is therefore suggestive, rather than conclusive, of substitution away from more capital-intensive activity.

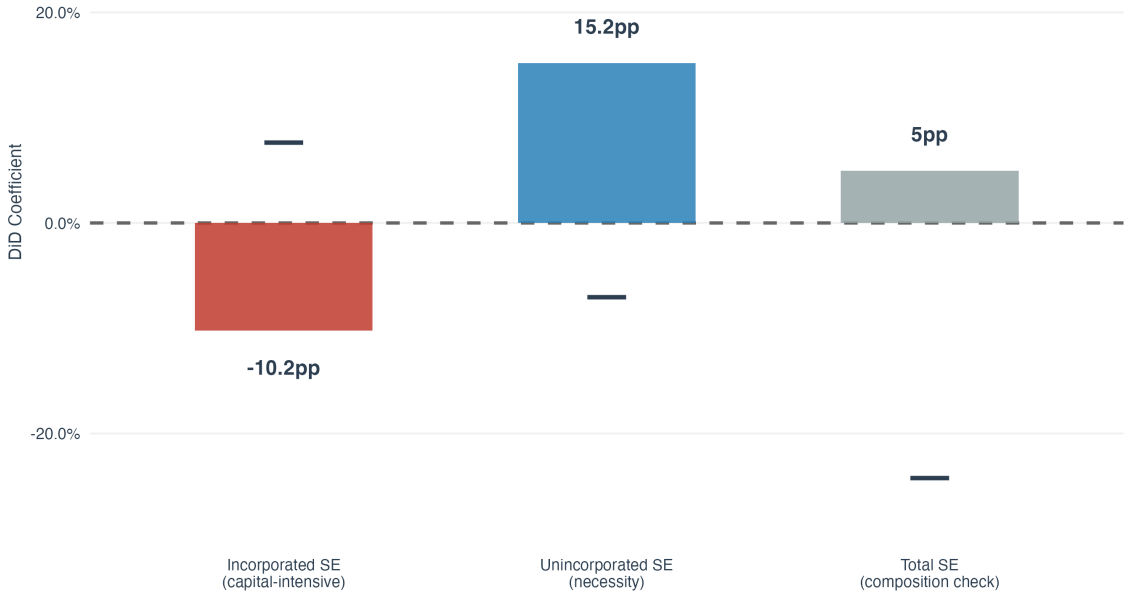

Figure 3: Substitution across self-employment types

5 Robustness and Heterogeneity

We incorporate multiple robustness checks to ensure the validity of our main model results (Appendix B Table 6):

1. First, excluding 2020 does not materially alter the estimated effect. The coefficient remains negative and of similar magnitude, suggesting that the main finding is not driven by differential responses during the pandemic period. This is important because 2020 represents a potential confounding shock to labour market behaviour, household finances, and self-employment decisions.

2. Second, we estimate a placebo test that assigns treatment to 2022 and excludes 2023 from the sample. The placebo coefficient is not statistically significant, thereby reducing concern that the estimated decline in incorporated self-employment reflects an unrelated structural break at the 2022–2023 boundary rather than the repayment-restart environment itself.

3. Third, we explore the timing issue within 2023 descriptively by separating January–May, June–September, and October–December. In our sample, heavily indebted borrowers exhibit no incorporated self-employment across

these sub-periods. While this does not allow a formal decomposition of the effect into anticipatory and realised-payment components, it reinforces the interpretation of the annual 2023 estimate as a reduced-form effect of the broader restart environment rather than a narrow October-only shock.

4. Fourth, we estimate a continuous-intensity specification within the borrower sample, interacting pre-period log debt with the post indicator. This produces no statistically meaningful dose-response relationship, suggesting that the key contrast may lie between heavily indebted borrowers and non-borrowers rather than in proportional variation in debt levels within the borrower sample.

5. Finally, the pattern across outcomes provides an additional check on interpretation. Incorporated self-employment falls, unincorporated self-employment rises in sign, and total self-employment remains close to zero. This pattern is more consistent with reallocation across forms of self-employment than with a general collapse in work activity among heavily indebted borrowers.

We disaggregate the sample by subgroup (Appendix B Table 7). The estimated decline in incorporated self-employment is larger among homeowners than among renters, which is consistent with the idea that borrowers facing greater fixed financial commitments may have been more exposed to the restart. However, these estimates are imprecise and not standalone findings. Additionally, net worth and education groups show similar directional patterns but are also limited by sample size. We therefore treat the heterogeneity analysis as supporting evidence for our main result.

6 Limitations

We identify three main limitations. First, incorporated self-employment is a low-frequency outcome and falls to zero among heavily indebted borrowers in 2023. This raises concerns about sparse-data bias, as estimates may be driven by few observations, leading to high variance and unstable coefficients. Second, the data does not extend beyond 2023. Since repayment resumed late in the year, the analysis captures short-run responses rather than fully realised adjustments. It is therefore not possible to determine whether the decline reflects a permanent effect or a delay in entry. Finally, student debt is not randomly assigned. High-debt individuals may differ systematically from non-borrowers in unobserved traits such as risk preferences or career choices. While the empirical strategy addresses observable and time-invariant differences, some selection bias may remain.

7 Conclusion

This paper examines whether the 2023 student loan repayment restart reduced incorporated self-employment among heavily indebted borrowers. Using SIPP panel data and a difference-in-differences design, we find a negative effect concentrated among high-debt borrowers, with little evidence at above median levels. Event-study estimates show no differential pre-trends, and placebo tests rule out a spurious 2022–2023 break. Incorporated self-employment falls, unincorporated rises in sign, and total self-employment remains unchanged, consistent with reallocation across margins rather than a general labour market decline. Entropy-weighted and subgroup estimates are less precise, so the evidence should be interpreted as pointing in a common direction rather than uniformly confirming the effect. Because SIPP is analysed at the person-year level, we cannot separate anticipatory responses from realised payments, so estimates reflect the broader 2023 restart environment rather than October payments alone. Within those limits, the evidence suggests repayment resumption discouraged capital-intensive self-employment among heavily indebted borrowers and that expected debt-service burdens shape entrepreneurial choices before cash-flow effects are realised.

Table 6: Robustness Checks

	Dependent variable:					
	Incorporated Self-Employment					
	(1)	(2)	(3)	(4)	(5)	(6)
DiD Coefficient	-0.124^{*}	-0.092	-0.071	0.087	-0.005	0.001
	(0.054)	(0.088)	(0.065)	(0.066)	(0.009)	(0.014)
Sample	Full	Drop 2020	Pre-2023	Pre-2023	Borrowers	Borrowers
Entropy Wtd	No	Yes	No	Yes	No	No
Observations	2,347	2,166	1,956	1,956	1,821	1,821

Standard errors in parentheses. Singleton observations dropped by TWFE.

$^{*}p < 0.10$, $^{**}p < 0.05$, $^{***}p < 0.01$

Table 7: Heterogeneity Analysis (Appendix)

	(1)	(2)	(3)
Panel A: Homeownership			
Homeowners	−0.192		
	(0.151)		
Renters		0.016	
		(0.040)	
Panel B: Education			
Graduate degree	−0.235		
	(0.185)		
No graduate degree		−0.001	
		(0.033)	
Panel C: Net Worth Quartile			
Q1 (lowest)	0.038		
	(0.037)		
Q2		−0.020	
		(0.033)	
Q3			−0.063
			(0.064)
Q4 (highest)	−0.482		
	(0.310)		
Observations	453	453	453

Notes: TWFE entropy weighted throughout. Clustered standard errors at the person level in parentheses.
